Abstract

Objective: The aim of this work was to evaluate the potential changes in the ballistocardiogram (BCG) signal induced by different respiratory patterns and posture, by using the dynamic time warping (DTW) technique. *Approach:* BCG signals were recorded in a group of 20 healthy volunteers, simultaneously with an electrocardiogram (ECG). Two recordings, one in a supine (SUP) and one in a standing (ST) position, including spontaneous breathing, two 1 min apneas (at full and empty-lungs, respectively) and 30 s of Valsalva, were analyzed. A warped averaged waveform was computed for each phase, from which amplitude and temporal parameters were extracted to characterize each condition. *Main results:* Variations were found in both amplitude and duration of BCG-derived parameters among manoeuvres, especially when compared to spontaneous breathing, suggesting a complex interaction between intrathoracic pressure changes acting on venous return, together with the autonomic nervous system modulation on heart rate. The effect of a hydrostatic pressure gradient elicited by postural conditions was also evident. *Significance:* Posture and respiratory manoeuvres affect the BCG signal in different ways, probably as a result of changes induced in preload and afterload. This supports the need to

define separate normality ranges for each posture and/or breathing conditions, as well as the importance of applying specific manoeuvres to highlight any pathological response in the computed BCG parameters.

Keywords: ballistocardiogram (BCG), signal averaging, dynamic time warping (DTW), cardiac monitoring, respiration

1. Introduction

Ballistocardiography is a non-invasive technique that measures the heartbeat-induced mass movements of circulating blood and of the heart itself, generated by the acceleration of blood as it is ejected and moved to the aorta and the large vessels (Gubner *et al* 1953). It is represented by a succession of systolic (H, I, J, K) and diastolic (L, M, N) waves, describing the forces associated with the shifting of the centre of mass of the body throughout the cardiac cycle (Pinheiro *et al* 2010). The ballistocardiogram (BCG) signal has recently been reconsidered as a useful technique in the characterization of cardiac performance (Inan *et al* 2015), offering a simple, efficient and affordable solution for home e-health monitoring (Javaid *et al* 2016), potentially representing an important practice in the prevention and early detection of cardiac-related diseases.

Temporal parameters, such as the RJ interval (the time interval between the occurrence of the R-peak on the ECG signal and the corresponding J wave on the BCG), have been proposed as a surrogate for the pre-ejection period (PEP), to assess cardiac contractility non-invasively (Inan *et al* 2008, Etemadi *et al* 2011, Javaid *et al* 2016). On the other hand, the amplitude of the BCG signal, especially in systolic waves, is mainly correlated with cardiac output, cardiac force, and velocity of ejection (Starr *et al* 1939), and has been found to be an indicator of myocardial contraction force (Starr 1955, 1965).

However, the BCG quasi-periodic signal is characterized by a large inter-beat variability in its morphology (both in duration and in amplitude), mainly related to the respiratory activity and mediated by the autonomic nervous system, thus affecting both preload and afterload by changes in intrathoracic pressure.

In order to extract valuable information from the BCG signal, two approaches have been proposed: (1) to extract beat-by-beat series from short-duration (≥ 3 min) recordings in order to characterize time and frequency parameters of heart-rate variability (Shin *et al* 2011, Zhu *et al* 2012); (2) to average consecutive beats acquired over shorter sequences (< 1 min) in order to obtain a characteristic waveform from which to derive indices of cardiac performance (Etemadi *et al* 2011, He *et al* 2011).

With regard to the averaging of biological signals, three approaches are available: synchronous, template-based, and non-linear techniques. Synchronous averaging is extensively used when a stimulus is present and the system's response is supposed to be stationary, where the waveforms are averaged after being aligned with respect to a reference point (Cohen 1986). The template-based approach is based on *a priori* selection of a reference waveform (i.e. the template) which is used to filter out non-similar waveforms from the signal, resulting in the averaging of the remaining similar ones (Aunon *et al* 1980). Finally, non-linear averaging techniques have been proposed to overcome limitations of the previous methods, in particular when dealing with quasi-periodic biological signals, whose morphology varies both in amplitude and in duration.

In particular, the dynamic time warping (DTW) technique, originally proposed with success for speech recognition (Sakoe and Chiba 1978), has been already applied to an echo-derived

left ventricular volume signal for the assessment of its function (Caiani *et al* 2002). The potential of this technique is that it allows the averaging operation to be performed after finding the best alignment between consecutive waveforms, thus compensating for temporal distortions without any *a priori* information.

We hypothesised that the use of the DTW algorithm could be successfully applied to the BCG signal to obtain an average waveform from a sequence of consecutive beats, from which to extract amplitude and temporal parameters to characterize cardiac performance.

In order to define a proper acquisition protocol that could then be implemented in a home-monitoring scenario, our aim was to evaluate the potential changes in the BCG signal induced by different postural conditions, as well as during different respiratory manoeuvres.

2. Materials and methods

2.1. Study protocol and population

Three-orthogonal components of the BCG signal, denoted as AP (Anterior-Posterior), LR (Left-Right, mediolateral), and HF (Head-Foot, longitudinal), were acquired (sampling frequency 960 Hz) by using a multicomponent biomechanical force plate, based on 3D piezoelectric load cells (Type 9286B, Kistler®, 600 × 400 mm), placed on the floor with its top surface 40 mm above floor level. The experimental set-up also included a rigid wooden platform (length 2100, width 400, height 40 mm) placed over the force plate, with its centre corresponding to the centre of the force plate and parallel to the horizontal plane, in order to avoid any contact with the floor. Forces induced by the body mass micro-displacements were directly transferred to the force plate, this being able to capture magnitude changes as small as 0.01 N. An offset-reset of the force platform was performed at the onset of each acquisition, allowing both the body weight and the wooden platform weight (i.e. the continuous signal component) to be automatically removed.

Simultaneously, a standard three-lead ECG signal was collected by a portable system (Porti TMSiTM, sampling frequency 2048 Hz). The ECG and BCG signals were synchronized by using a TTL function generator that sent a signal simultaneously acquired by both systems.

Subjects were first asked to stay in a supine (SUP) position, with their centre of mass aligned with the central point of the force plate (figure 1(a)), and then in a standing (ST) position, with their feet centrally positioned (figure 1(b)). Our acquisition protocol included two consecutive recordings (SUP and ST, respectively), each consisting of:

- (a) 5 min at resting conditions;
- (b) 3 preparatory deep breaths;
- (c) 1 min apnea at end-inspiration (Full-lung apnea);
- (d) 1 min of normal breathing;
- (e) 3 preparatory deep breaths;
- (f) 1 min apnea at end-expiration (Empty-lung apnea);
- (g) 1 min of normal breathing;
- (h) 30 s of Valsalva manoeuvre.

Subjects were asked to stay quiet and not to make any voluntary movements throughout the acquisition period, in order to minimize motion artefacts and to ensure that the signal oscillations were mainly due to mass motion inside the body.

The analysed population was a group of 20 healthy volunteers (12 females) whose main characteristics are summarised in table 1.

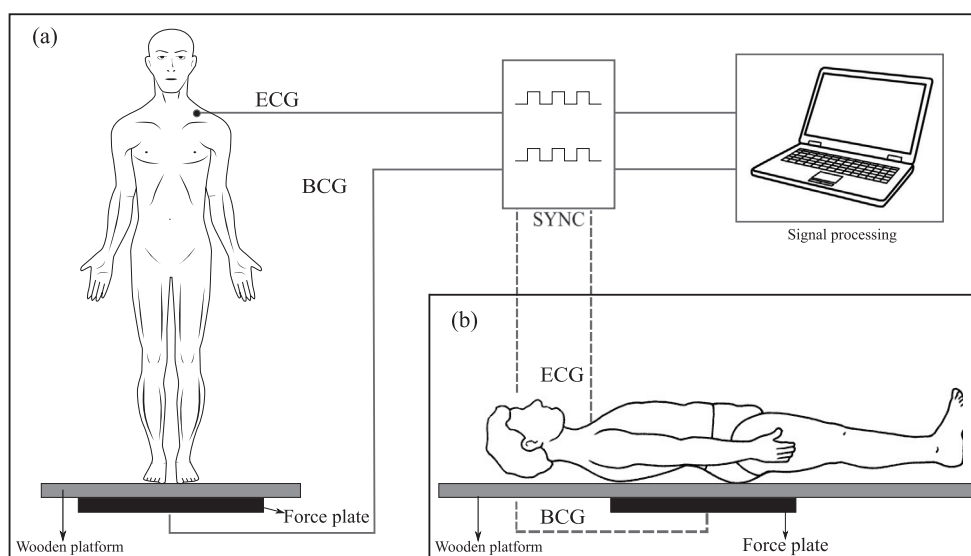

Figure 1. Schematic of the experimental set-up for the subject in standing position (a) and supine (b).

Table 1. Study population characteristics expressed as mean \pm std.

Variable	Males	Females
Age (years)	32.9 \pm 9.0	28.2 \pm 4.8
Weight (kg)	72.9 \pm 10.5	53.9 \pm 8.3
Height (m)	1.79 \pm 0.08	1.62 \pm 0.06
BMI (kg m ⁻²)	22.8 \pm 4.06	20.6 \pm 2.13

BMI: body mass index.

All participants gave written informed consent to participate in the study. The experimental procedures involving healthy volunteers described in this paper were in agreement with the principles outlined in the Helsinki Declaration of 1975, as revised in 2013. Ethical committee approval of the Université Libre de Bruxelles, Hôpital Erasme, was obtained prior to the study.

2.2. Pre-processing

The pre-processing stage included automatic QRS detection from the ECG signal using a wavelet-based ECG delineator (Martinez *et al* 2004), followed by ECG-BCG synchronization using the trigger signal. The BCG signal was then filtered (band pass, 0.1–30 Hz, Butterworth filter, order 8) in order to remove baseline wander, noise, and other out-of-band components (high-frequency motion artifacts).

Figure 2 shows an example of the three-orthogonal filtered components of the reaction force from a representative subject, in supine (upper panel) and standing (bottom panel) positions, synchronized with the ECG signal. In both postures the best signal-to-noise ratio, and the most informative content showing the quasi-periodic heart-induced activity, was visible in the longitudinal head-to-foot (HF) component. Based on this consideration, together with the fact that it has been the most widely-studied component and the only one for which an interpretation has been provided, we focused our attention on this component only.

Figure 2. Example of synchronized ECG and the three components of the BCG signal: HF (head-to-foot), AP (antero-posterior) and LR (left-to-right) components, in both supine (left) and standing (right) positions.

Finally, BCG segments of the acquisition relevant to phases (a), (c), (f) and (h) of the protocol were extracted. R-peak events on the ECG were utilized to delimit each BCG cardiac cycle.

2.3. Dynamic time warping

The DTW averaging technique (Sakoe and Chiba 1978) comprises the iterating of two consecutive steps performed on pairs of BCG waveforms, each representing one cardiac cycle, according to a binary tree combination procedure:

1. the calculation of the time-warping function (TWF) to perform the best alignment between their temporal axes, and;
2. the computation of a new waveform by mixing and averaging the values from the two original cycles, according to the TWF.

2.3.1. Calculation of the TWF. A more detailed description of the computation of the TWF can be found elsewhere (Caiani *et al* 2002). Summarizing, given two BCG waveforms, $S_x(n)$ and $S_y(m)$, with different durations ($1 \leq n \leq N$ and $1 \leq m \leq M$, respectively) but equally sampled, the temporal correspondence between samples of S_x and S_y is defined by the monotonic and continuous TWF, matching the time axis n of the waveform S_x in the time axis m of the waveform S_y , and vice-versa. Figure 3 shows an example of the TWF represented in the plane (n, m) , with the patterns S_x and S_y on the n and m axes, respectively.

To calculate the TWF, the following measure of dissimilarity (i.e. the local cost) between the normalised waveforms S_x and S_y was utilised, as described in Caiani *et al* (2002), taking into account their amplitude and first derivative differences:

$$d(n, m) = k_1 |S_x(n) - S_y(m)| + k_2 |\dot{S}_x(n) - \dot{S}_y(m)|$$

with $k_1 = k_2 = 1$, and \dot{S} representing the first normalized derivative. The value of $d(n, m)$ is computed at every point of the warping plane (n, m) that lies inside the zone of the plane (n, m)

Figure 3. Example of the computed time-warping function (TWF) that best aligns the two consecutive BCG normalized waveforms, here denoted as $S_x(n)$ and $S_y(m)$. The red cross represents the correspondence between the two J positive waves in both waveforms (samples $n = 218$ and $m = 234$, respectively).

around the main diagonal, defined as $|n - m| \leq r$, where $r = 10 + |N - M|$, thus preventing excessive adjustment of the time axes.

Then, given the local dissimilarity $d(n, m)$, by a dynamic programming algorithm (Sakoe and Chiba 1978) a cost matrix D was computed using the symmetric form without slope constraints (Sakoe and Chiba 1978), where $D(n, m)$ represents the minimum cumulative cost to reach the point (n, m) starting from $(1, 1)$:

$$D(n, m) = \min \{D(n, m - 1) + d(n, m), D(n - 1, m) + d(n, m), D(n - 1, m - 1) + 2d(n, m)\}$$

with the initial condition of $D(1, 1) = 2d(1, 1)$ and boundary conditions of $D(n, 1) = D(n - 1, 1) + d(n, 1)$ and $D(1, m) = D(1, m - 1) + d(1, m)$. The TWF is finally derived as the path with minimum cost from $(1, 1)$ to (N, M) .

2.3.2. Computation of the averaged waveform. The warped average (WA) between two consecutive BCG cycles was computed according to the TWF as described in Caiani *et al* (2002), resulting in a waveform of duration equal to $(N + M)/2$. The final WA is computed from a set of L consecutive cycles, with L being an integer to the power of two. Waveforms are grouped in $L/2$ pairs, resulting in $L/2$ WAs being computed. Then, this step is iterated until just one final WA beat is obtained.

Figure 4. Example of a sequence of 32 BCG waveforms (light grey) obtained in one subject, with the results of their synchronous averaging (blue dashed line) and of the DTW averaging (blue line).

To compare the effects of the different manoeuvres, $L = 32$ consecutive beats were considered for each phase of the protocol (number limited by the shortest phase that is the 30s Valsalva manoeuvre stage). Figure 4 shows an example of the original 32 consecutive beats obtained in a subject in a standing position during the resting period, together with the corresponding synchronous averaging (blue dashed line) and the final warped average (blue line). It can be seen how the characteristic peaks of the BCG signal were maintained, especially during the diastolic phase, by the proposed DTW averaging technique, despite differences in both amplitude and duration among the considered waveforms. As expected, amplitude and temporal position of the H, I, J, K peaks appeared dependent on the utilized averaging approach.

2.4. Fiducial points detection

For each phase of the protocol, that is, resting, full-lung apnea (Full), empty-lung apnea (Emp) and Valsalva (Val), the respective WA waveform was computed.

As the WA represents the temporal average of the 32 consecutive beats, the duration of the template defines the average RR interval. Systolic fiducial points were then identified on each final WA waveform, as shown in figure 4: according to Pinheiro *et al* (2010) the H wave represents the first positive peak, synchronous with the isovolumetric contraction; the I wave, which is the first negative wave at the onset of ejection (early systole), corresponds to blood acceleration in the ascending aorta and pulmonary arteries; the J wave, the main positive wave occurring late in systole, corresponds to blood acceleration when ejected into the descending aorta; and finally, the K wave corresponds to the second negative deflection associated with the descending slope of the femoral pulse, synchronized with the second heart's sound, and so with closure of the semilunar valves. The RK interval represents the systolic phase, while the complementary KR interval represents the diastolic period.

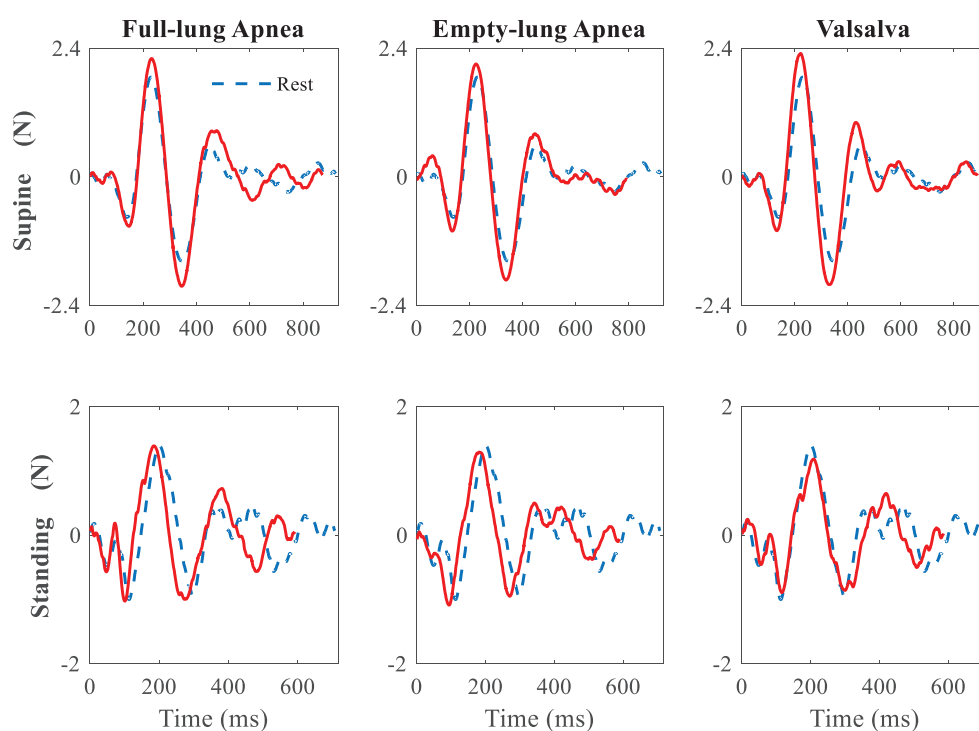

Figure 5. An example of warped average waveforms computed from one subject at each respiratory condition in both supine (upper panels) and standing (bottom panels) positions. The blue dashed line corresponds to the WA at Rest condition.

The following temporal parameters were extracted and normalized by the corresponding RR duration, in order to describe the relative time occurrence of the main BCG events: RI, RJ, RK and IK sub-intervals. In addition, the peak-to-peak amplitude parameters A_{HI} , A_{IJ} and A_{JK} were computed. They are inertial forces in nature, so it was deemed reasonable to normalize them by the subject's body mass index (BMI).

2.5. Statistical analysis

Due to the non-Gaussian distribution of the temporal and amplitude parameters, data are presented as median and 25th and 75th percentiles, unless otherwise specified. To evaluate changes in BCG signals induced by the imposed breathing manoeuvres, a non-parametric paired Wilcoxon rank test was applied to both the temporal (RR, RI, RJ, RK and IK) and the amplitude parameters (A_{HI} , A_{IJ} and A_{JK}) to compare the resting condition and each of the breathing manoeuvres: full-lung apnea, empty-lung apnea, and Valsalva. To test the effects of posture, a non-parametric paired Wilcoxon rank test was also applied between the corresponding SUP and ST values for each parameter. Additionally, the same test was applied to test the null hypothesis that empty- and full-lungs apneas generated a similar response on the examined parameters. The null hypothesis was rejected when $p \leq 0.05$.

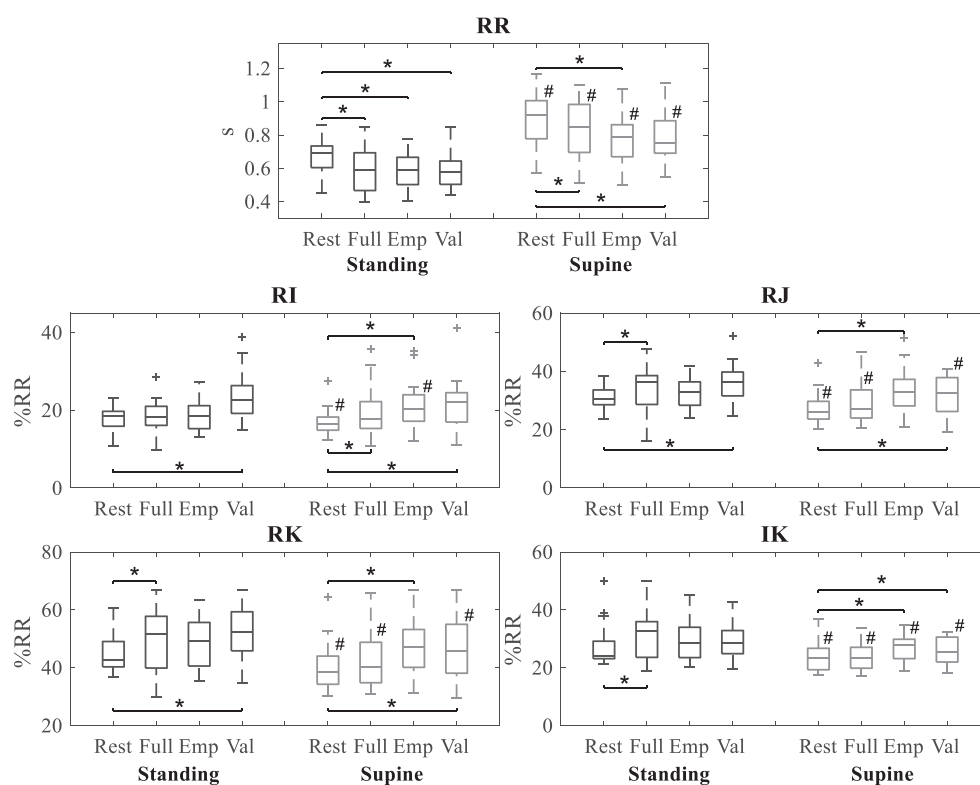

Figure 6. Results of RR and normalized sub-intervals obtained in the normal population of 20 subjects represented as Whisker plots. *: $p \leq 0.05$ versus Rest; #: $p \leq 0.05$ SUP versus ST.

3. Results

An example of the WA computed in one subject and during each of the studied manoeuvres and postures is shown in figure 5. In each panel, the red waveform corresponding to each different tested condition is superimposed on the waveform corresponding to the spontaneous breathing (Rest) condition, represented as a blue dashed line. In this case, it is possible to observe how the RR duration was reduced in the ST posture compared to the SUP posture. In all cases it was also longer in Rest than in the other breathing manoeuvres, as expected from physiology.

The results of the studied normal population in terms of normalized BCG sub-intervals and peak-to-peak amplitudes are shown in figures 6 and 7, respectively, while their absolute values are reported in table 2.

As previously observed, the RR interval was shortened for each respiratory manoeuvre with respect to the Rest condition, with significantly shorter values in the ST posture than in SUP, as expected (see figure 6, upper panel).

Regarding BCG-derived normalized sub-intervals, in the SUP posture the respiratory manoeuvres affected the I, J and K time occurrence by prolonging the corresponding temporal parameters in empty-lung apnea (RI + 19%, RK + 15%, RJ + 16%, IK + 11%) and Valsalva (RI + 26%, RK + 13%, RJ + 21%, IK + 11%), expressed as a percentage variation compared to the Rest value, while full-lung apnea affected only RI (+7%).

Table 2. Sub-intervals and peak-to-peak amplitudes in absolute values, expressed as median (25th, 75th percentile), for each posture (supine and standing, SUP and ST respectively) and during each manoeuvre (rest, full-lung and empty-lung apneas and Valsalva).

^a $p \leq 0.05$ versus Rest.

^b $p \leq 0.05$ SUP versus ST.

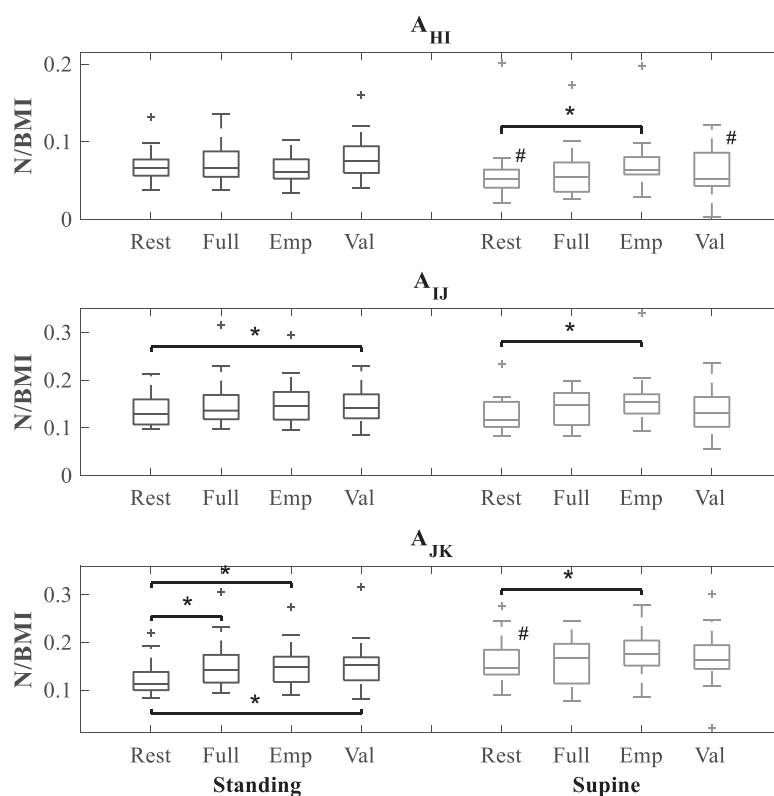

Figure 7. Results of normalized peak-to-peak amplitudes obtained in the normal population of 20 subjects represented as Whisker plots. *: $p \leq 0.05$ versus Rest; #: $p \leq 0.05$ versus Standing.

In the ST posture, empty-lung apnea did not significantly modify any parameter, while full-lung apnea prolonged all sub-intervals (RK + 9%, RJ + 9%, IK + 10%) except RI. In the same posture the Valsalva manoeuvre prolonged all sub-intervals (RI + 24%, RK + 17%, RJ + 11%) except IK. When comparing SUP versus ST conditions, the majority of parameters resulting were shorter for SUP. This was particularly evident for the IK interval, which was always shorter in SUP than in ST.

Finally, when comparing the two apneas (Full and Emp), all temporal parameters (RR, RI, RJ, RK, IK) were significantly different between these two conditions ($p < 0.05$ in all cases) in the supine position, whereas no significant differences were found while standing.

As regards normalized peak-to-peak amplitudes, in SUP the only respiratory manoeuvre that affected all the indices compared to Rest was the empty-lung apnea ($A_{HI} + 25%$, $A_{IJ} + 17%$, $A_{JK} + 17%$).

In the ST posture, A_{HI} was unchanged, A_{IJ} increased by 13% only with Valsalva, while A_{JK} increased by 20% as a result of each manoeuvre. Compared to ST, the main differences in SUP were found in Rest, with a decrease in A_{HI} and an increase in A_{JK} peak-to-peak amplitudes. In addition, A_{HI} was found to decrease during the Valsalva manoeuvre.

4. Discussion and conclusion

Ballistocardiography was originally proposed as a diagnostic tool to study cardiac mechanics and obtain information about cardiac contractility by measuring the shifting in the body mass centre due to displacements of the heart, as well as of the blood masses in the vessels due to cardiac contractions (Starr *et al* 1939, Gubner *et al* 1953, Starr 1955, 1965). However, the limited technology available during its early development and the large inter-subject variability of the signal impeded the achievement of a generalized usage.

More recently, new developments in accelerometer technology and hardware miniaturization have led to the reconsideration of BCG as a potentially useful non-invasive methodology with which to characterize cardiac performance (Inan *et al* 2015). In fact, this technique potentially offers a simple, efficient and affordable solution for home e-health monitoring as it can be embedded in commonly used objects (e.g. weight scales, bed, chair). In particular, the RJ interval has been proposed as a surrogate for the pre-ejection period (PEP) (Inan *et al* 2009, Etemadi *et al* 2011, Javaid *et al* 2016), a non-invasive indirect measurement of cardiac contractility (Lewis *et al* 1977), and, combined with photoplethysmography (PPG), both I and J time occurrences have been shown to be an accurate estimate of arterial stiffening (Wiard 2012).

At this point, it becomes important to define a range of values from a normal population for both temporal and amplitude parameters that can be extracted from the BCG, and to study their changes related to posture or respiratory manoeuvres. This information could reveal its utility in the definition of a specific acquisition protocol, and reveal pathologic or physiologically-induced alterations.

In our work, we aimed at studying the BCG signal obtained by a force platform in a population of normal subjects in different cardiac preload and afterload conditions, as well as different autonomic control activities, by means of changes in posture (supine and standing) and by different simple respiratory protocols (normal breathing, apnea and Valsalva).

Indeed, respiration is one of the strongest modulators of cardiac function, as a consequence of changes in intra-thoracic pressure and systemic venous return (Guyton and Hall 2006). In particular, with the Valsalva manoeuvre a sequence of rapid changes in preload and afterload stress is induced. More precisely, it has a direct influence on the pattern of the cardiovascular system, whose response has been reported to be subdivided into four phases (Hamilton *et al* 1936, Looga 2005). In the early phases of strain (I–II), the increase in intra-thoracic pressure results in a concomitant increase in both heart rate and blood pressure (Porth *et al* 1984); this is followed by an increase in parasympathetic activity after strain release (phases III and IV), resulting in a decrease in heart rate.

Apneas performed at end-inspiration and at end-expiration are related to different intra-thoracic pressures and non-modulated venous return, providing the possibility to acquire the BCG signal in a relatively steady-state condition. However, the cardiovascular response during these manoeuvres has been reported to be variable over time. Javorka and colleagues showed how an empty-lung apnea induced an initial tachycardia in the first 10 s approximately, followed by a compensatory decrease in heart rate, evaluated in 24 young healthy volunteers while in a sitting position (Javorka *et al* 2001). The results of our work revealed that the empty-lungs apnea resulted in a different outcome in temporal parameters than for full-lung apnea, but only in the supine position. This could be due to the fact that in standing, the initial control condition before the apnea was already manifesting a sympathetic activation (median RR_{rest} = 675 ms in standing, versus 922 ms in supine), thus limiting the additional effects of the provoking manoeuvre.

Our results confirmed that acquisition of BCG from a piezoelectric load cells force platform was feasible in all subjects, and signal quality allowed for further analysis and automated parameters extraction in both examined postural conditions.

The acquired BCG is a quasi-periodic signal characterized by a large inter-beat variability in morphology (both in duration and in amplitude). Based on these signal characteristics, DTW was selected as the most appropriate averaging method and was applied to 32-beat sequences obtained during the different breathing manoeuvres imposed. This number of consecutive beats was determined as a compromise between the requirement of acquiring an adequate number of waveforms to be included in the warped averaging in order to improve the signal-to-noise ratio, and the need to keep as short as possible the acquisition in an hypothetical user-driven scenario in which the subject has to maintain the suggested posture for a limited time, both during spontaneous breathing and respiratory manoeuvres. In particular, during the Valsalva manoeuvre, this choice resulted in the focusing of our analysis on the effects relevant to the early phases of the cardiovascular response. Also, for apneas, the choice to limit our analysis to the first 32 beats acquired during this manoeuvre led to a predominance of the initial tachycardia in the observed results. To our knowledge, this is the first time that a DTW technique has been applied to the BCG signal with the goal of generating normality ranges in different postural and breathing manoeuvres.

The DTW method resulted in an averaged waveform in both duration and amplitude from which both temporal and peak-to-peak amplitude parameters were automatically extracted. In order to obtain a range of comparable results representative of the studied normal population, two different normalizations were introduced. For temporal indices, each sub-interval parameter was normalized by the corresponding heart beat duration; for amplitude indices, each peak-to-peak parameter was normalized by the subject BMI. Normalization by the heartbeat duration allowed for the pooling of subjects for comparison of temporal BCG parameters between SUP and ST postures, despite heart rate being found to increase while in a standing posture, as well as between the resting spontaneous respiration and each breathing manoeuvre. Similarly, normalization by the BMI was intrinsically corrected for possible inter-subject variability due to different stroke volume and cardiac output, thus allowing cumulative analysis without other distinctions (i.e. sex, body composition) (Collis *et al* 2001).

Obtained results showed modifications in both amplitude and duration of BCG-derived parameters among the respiratory manoeuvres, especially when compared to spontaneous breathing, but being also dependent on the assumed posture. The prolongation of the RJ interval during Valsalva, which could be explained as a consequence of the decreased venous return during the strain, was already reported in the literature (Inan *et al* 2008). However, this decrease in venous return was not visible in terms of amplitudes, in contrast to the reduced values of A_{IJ} reported in Inan *et al* (2009).

On the other hand, the observed reduction in the RJ interval from standing to supine is likely due to the increase in venous return associated with the supine condition, which is also manifested by a decrease in the pre-ejection period. This is in agreement with what was observed by McCall *et al* by studying subjects in a standing position on a weighing scale by comparing results on the ground and during microgravity induced by parabolic flight manoeuvre (McCall *et al* 2014). The increase in venous return as a characteristic of the supine condition, associated also with a larger stroke volume (Frey *et al* 1994), might also be reflected in the larger peak-to-peak A_{JK} amplitude as observed in the supine position compared to standing.

These observations demonstrate the complex interaction between intra-thoracic pressure changes acting on venous return, the effect of the hydrostatic pressure gradient elicited by postural conditions, and the autonomic nervous system modulation on the heart rate and peripheral baroreceptor reflex.

As these contributions cannot be easily disentangled, the availability of normality reference values for each condition to be used for comparison of new subjects assumes particular importance in the potential identification of possible pathologies involving mechano-electrical cardio-pulmonary coupling.

In conclusion, an acquisition protocol for the BCG signal that included different respiratory manoeuvres to be performed in standing and supine positions was implemented. The acquired signal was analyzed by DTW to compute normality ranges in both temporal and amplitude parameters, and to evaluate potential changes induced by the different settings. Results show dependency from respiratory manoeuvre and posture, supporting the need for the definition of separate normality ranges for each of the studied conditions, as well as the importance of applying specific manoeuvres to highlight any pathological response in the computed BCG parameters.
